A negative control that depends on the window: rheumatoid arthritis versus cancer

Three cells show no mismatch enrichment at any width. The other three rise as the window narrows, and two of them — melanoma on whole blood and RA on CD4⁺ T cells — trace almost the same curve. They differ in whether that enrichment reaches significance, not in its size.

RA × CD4⁺ is clean at exactly one setting: the registered one, at the coarse end. A wide window is where the control discriminates least — both lists hit a great deal and the ratio is diluted towards 1 — so the cell clears its negative control where that control is weakest. Hence the non-cancer result is reported as descriptive.
